Abstract

Energy harvesting is an increasingly attractive source of power for cellular networks, and can be a promising solution for green networks. In this paper, we consider a cellular network with power beacons powering multiple mobile terminals with microwave power transfer in energy beamforming. In this network, the power beacons are powered by grid and renewable energy jointly. We adopt a dual-level control architecture, in which controllers collect information for a core controller, and the core controller has a real-time global view of the network. By implementing the water filling optimized power allocation strategy, the core controller optimizes the energy allocation among mobile terminals within the same cluster. In the proposed green energy cooperation paradigm, power beacons dynamically share their renewable energy by locally injecting/drawing renewable energy into/from other power beacons via the core controller. Then, we propose a new water filling optimized green energy cooperation management–strategy, which jointly exploits water filling optimized power allocation strategy and green energy cooperation in cellular networks. Finally, we validate our works by simulations and show that the proposed water filling optimized green energy cooperation management strategy can achieve about 10% gains of MT's average rate and about 20% reduction of on-grid energy consumption.

---

1. Introduction

The continuous development of wireless communication technology combined with the deep optimization of the network has resulted in an exponential growth of mobile data traffic, which has contributed to a rapid increase in the energy consumption and carbon emission of the information and communication technology (ICT) sector. It is estimated that, in 2020, the annual carbon emission of the ICT industry will be 235 Mto [1] and the electric energy consumption will be 414 Twh [2]. This not only leads to enormous network operation cost, but also places heavy burdens on grid and the environment. Thus, reducing power consumption of the infrastructure within the system is crucial to cellular networks.

Multiple studies are providing strong support that the use of harvested renewable energy reduces the carbon footprint and on-grid power consumption of the cellular networks [3]-[5]. That because exploiting renewable energy to power facilities of cellular networks can reduce on-grid energy consumption. Energy harvesting (EH) from renewable energy sources (e.g., solar, wind, vibration, ambient radio power, etc.) is emerging as a practically appealing solution to prolong the lifetime of energy-constrained wireless networks [6], [7]. At the same time the renewable energy is more economical and green than conventional energy that generated from fossil fuels etc. [8], [9]. By introducing the harvested renewable energy to power the next-generation cellular networks, potentially 20% of CO_2 emission can be reduced [10].

To enjoy the environmental friendliness and low-cost of the renewable energy, EH is an ideal solution. However, owing to the space-time instability and non-uniformity of green energy, it may not guarantee sufficient power supplies for facilities in the cellular networks. Thus, to overcome the unreliability of the renewable energy source, hybrid cellular networks powered by multiple types of energy supply (e.g., the on-grid energy, the solar energy, and the wind energy), where EH and the grid coexist, will be an ideal solution [4], [11]. In such cellular networks, the system is powered by renewable energy if the green energy collectors can gather enough power; otherwise, the facilities switch to on-grid energy.

With the development of energy harvesting circuit, power transfer in wireless communication systems has drawn significant attention. [12] propose a new network architecture for radio frequency charging stations, overlaying with an uplink cellular network. The paper described an energy transfer wireless communication system, in which energy can be delivered via microwave power transfer (MPT). The capability allows the wireless devices to harvest energy from microwave signals for information processing and transmission. We can use MPT to charge mobile terminals (MTs) and get rid of power cords. The study extended to a harvest-then-transmit architecture for power transfer in wireless broadcast system [13]-[15], and energy cooperation systems [16]-[25]. The works are studied in different system model and scenarios. In [13] the multi-antenna access point first broadcasts wireless power to all users via energy beamforming in the downlink, and then, the users send their independent information to the access point simultaneously in the uplink using their harvested energy. [14] lets the source and relay harvest energy from the access point in the downlink and work cooperatively in the uplink for the source's information transmission. [15] characterizes the spectral efficiency of an uplink radio frequency-powered macrocell network that the users transmit in the uplink while replenishing energy from base station in the downlink. [16] proposes an energy cooperation save-then-transmit scheme in a point-to-point wireless

communications system, where energy is allowed to flow between the transmitter and receiver. A practical coordinated multipoint system with clustered base stations cooperatively communicating with mobile terminals is considered in [17] and [23]. [18] studies a model for energy cooperation between cellular base stations with hybrid power supplies, limited energy storages, and connected by resistive power lines for energy sharing. A cooperative mechanism for wireless energy harvesting and spectrum sharing in 5G networks is studied in [24], where secondary users harvest energy from both ambient signals and primary user's signals and can act as relays. [25] analyzes a cooperative energy efficiency model in cellular network under different cooperative transmission scenarios, interference levels and wireless channel conditions. Assuming the future channel side information is available, the maximum throughput of point-to-point EH fading channels can be achieved by the directional water filling algorithm [26]. For wireless networks with hybrid energy sources, a power allocation algorithm was proposed in [27] to achieve energy cost minimization. [28] shows us an optimal power allocation policy to minimize the conventional energy consumption with delay-constrained data traffic requirement in heterogeneous cellular networks. Transmission protocols for cellular networks with hybrid power supplies have also been studied in [4], [9], [11], [28], [29]. However, as the harvested green energy is snatchy and sporadic, the design of the network setting is challenging. Energy management decision in EH networks should be based on both the channel side and the energy side adaptively. Thus more decisions must be made, and more information will be needed.

In the prior works, the network's parameters can't be changed dynamically and a suitable strategy can't be chosen according to the variation of the channel state information (CSI) of the system. Moreover, in [12] all power beacons (PBs) have to deliver energy to MTs with the same transmission power, no matter how far the distance between PB and MT is. Much energy has been wasted, and due to the high energy transfer the addictive white noise is increased, both of them do harm to the performance of the system. To achieve agile response to the changes of the CSI, and overcome the shortage of non-adjustable transmission power of PB, in this paper, we introduce a dual-level control architecture to detect and manage the system dynamically. In the architecture, controllers are responsible for gathering information for a core controller (CC), and the CC grasps the entire system. After processing the collected data, the CC can adjust the parameters of the network according to the conditions of the system and send commands to PBs dynamically. We propose a power allocation optimization approach for cellular networks with hybrid energy supplies as shown in **Fig. 1**, where stations named PBs are deployed in an existing cellular network for recharging MTs via MPT wirelessly. Each PB is equipped with a solar panel and connected to grid by the CC, so PBs can be powered by hybrid power supplies. With the CC, PBs can get conventional energy from grid if the renewable power is insufficient, and achieve green energy cooperation.

In this work, we will develop effective power allocation optimization and green energy cooperation algorithm to improve the performance of cellular networks powered by hybrid energy sources. Our contributions can be summarized as follow:

- We propose a dual-level control architecture, in which controllers collect information for the CC, and the CC manage the entire system. The performance of the network can be improved by the dual-level control architecture.

- A low-complexity online water filling optimized power allocation strategy (WFOPAS) is proposed for maximizing the uplink rate. With the algorithm, the MT's average rate can be improved obviously.

● We further propose a green energy and CSI aware scheme, that named water filling optimized green energy cooperation management strategy (WFOGECMS). With the scheme, the preference of the system can be improved. Moreover, the algorithm does not require statistical CSI and EH processes, which makes it applicable in unpredictable environment.

● Simulation results are provided to certify the theoretical analysis. It shows that, with renewable energy distributed unevenly, the WFOGECMS algorithm not only achieves the MT's average rate improvement, but also reduces the on-grid energy consumption.

The paper is organized as follows. Section 2 defines the system model. Section 3 formulates the uplink rate maximization problem. Section 4 proposes the WFOGECMS algorithm for the uplink rate maximization problem. Section 5 provides simulation results, and conclusions are presented in Section 6.

2. System Model

This section describes the definitions and assumptions of the network, and explains how the system deals with wireless power transfer and communication. The system model is illustrated in **Fig. 1**, and the notation is summarized in **Table 1**.

Fig. 1. System model

In our model, multiple base stations, PBs and MTs are independent with each other, and MTs have been divided into clusters corresponding to PBs. We focus on maximizing the

uplink rate by designing the renewable energy and CSI aware scheme. In the dual-level control architecture, controllers are configured on base stations, gathering information relying on the base stations' coverage of the area. Information collected by controllers consists of: the position of PBs and MTs, the amount of harvested green energy, each MT's access status with PB and base station, and the CSI information. The CC, which connects to controllers (by its connection with base stations) and PBs by cables, responsible for complex calculation, and has a global grasp of the system. After analyzing the gathered data, the CC sends commands to PBs. According to the commands of the CC, PB can optimizes power allocation among its antennas, and green energy cooperation can be implemented by PBs locally injecting/drawing power into/from other PBs via the CC. The CC controls the direction of energy flow that exchange among PBs. Under the priority use of renewable energy, the shortage is supplemented by grid.

Furthermore, we assume para-static time-slotted model for both renewable energy and equivalent channels (there are two types of wireless channels in the network: the energy link and the data link, we collectively name them as the equivalent channel). The energy harvesting rate and the channel coefficient remain constant in each slot and may change from one slot to another. Without loss of generality, we choose one communication block as the reference time slot. We focus our study on one communication slot. In the following, we will present the energy model and the uplink cellular network model.

Table 1. Summary of notations

Symbol	Meaning
N, M, S	The total number of PBs, MTs, base stations
E_i, M_i	The harvested renewable energy by PB_i, the number of MTs served by PB_i
Q	The total harvested renewable energy
p_i	The power consumption of PB_i
$p_{i,k}$	The transmission power from the PB_i to its k-th MT
E_i^+, E_i^-	The renewable energy drawn/injected by PB_i
ζ	Energy transfer efficiency
P_i^G	The consumed on-grid power by PB_i
d, D	The Euclidian distance between MT and its PB, MT and its base station
U_0, P_0, B_0	The typical mobile terminal, base station and power beacon
$q_{u_0}^r$, $q_{u_0}^t$	The receiving, transmission power of the typical mobile terminal
$q_{B_0}^r$	The receiving power of the typical base station
α, β	Path-loss exponent for a MPT channel, data channel
G_m	The amplify factor in energy beamforming
σ^2	The white noise variance
ϑ	The threshold of the signal to interference plus noise ratio
ε	The power sensitivity of energy harvest
f	The coefficient of channel fading
B	The bandwidth of a base station

2.1 The Energy Model

We consider a system with N PBs, M MTs, S base stations. Each PB is equipped with H ($H \in Z \,\&\, H > 1$) antennas. Because of multiple antennas PB has, it can charge multiple target MTs simultaneously. PBs are distributed uniformly, and are independent with base stations and MTs. The number of MTs is no larger than the total number of PBs' antennas, i.e., $M \leq NH$. We denote the set of PBs and that of MTs as $\mathcal{N} = \{1, ..., N\}$ and $\mathcal{M} = \{1, ..., M\}$, respectively.

As show in **Fig. 1**, PBs are powered by grid and green energy simultaneously. MT is powered by the nearest PB with energy beamforming. Base stations are powered by grid and just receive information from MTs. For convenience, we neglect the static energy consumption of PBs, base stations, MTs, controllers, and CC as [17] did. We consider the power management in PB_i as shown in **Fig. 2**. BP uses renewable energy that is locally harvested or transferred from other PBs preferentially, otherwise, it consumes the on-grid power. The harvested renewable energy at PB_i ($i \in [1, N]$) is denoted by E_i, and

$$\sum_{i=1}^{N} E_i = Q \tag{1}$$

$$E_i \geq 0, \quad \forall i \in [1, N] \tag{2}$$

Where Q is the sum harvested renewable energy by PBs. We assume that $E_1, E_2, ..., E_N$ are independent and uniformly distributed in $[0, Q]$, each with an equal mean of Q/N. Note that the independent energy distribution may correspond to the case in which the PBs are in different position.

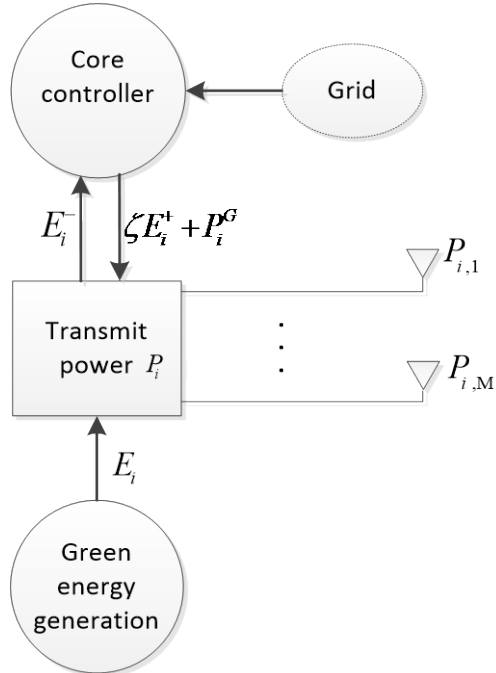

Fig. 2. Energy management schematics at PB_i

The power of PB_i consisted of four parts: the locally harvested renewable energy E_i, the drew/ injected green energy from/into other PBs via the CC $\zeta E_i^+ / E_i^-$, and the power from grid P_i^G. PB_i injected its locally harvested renewable energy into other PBs, only when its green energy is surplus. Set the number of MTs served by PB_i is $M_i \ (M_i \in Z, M \geq M_i \geq 0)$, the power consumption of PB_i can be given by

$$P_i = \sum_{k=1}^{M_i} P_{i,k} = E_i + \zeta E_i^+ - E_i^- + P_i^G \tag{3}$$

where $\zeta \in [0,1]$ is the efficiency coefficient of energy transfer, and Eq. (3) should satisfy the following constraints:

$$E_i^+ E_i^- = 0 \tag{4}$$

$$E_i^+ \geq 0, \ \forall i \in [1, \text{N}] \tag{5}$$

$$E_i^- \geq 0, \quad \forall i \in [1, \text{N}] \tag{6}$$

$$P_i^G \geq 0 \tag{7}$$

The proof of Eq. (4) is as follow.

By satisfying the constraints of Eq. (5) and Eq. (6), at least one of E_i^+ and E_i^- is zero. Because in real-time applications only three cases will be happening to PB_i:

$$\begin{cases} E_i^- > 0 \ \& \ E_i^+ = 0, & E_i - P_i > 0 \\ E_i^- = 0 \ \& \ E_i^+ = 0, & E_i - P_i = 0 \\ E_i^- = 0 \ \& \ E_i^+ > 0, & E_i - P_i < 0 \end{cases}$$

Where $E_i - P_i > 0, E_i - P_i = 0, and \ E_i - P_i < 0$ corresponding to three cases that the green energy of PB_i overflowing, exactly right, inadequate respectively. Above all, we can get $E_i^+ E_i^- = 0$, and Eq. (4) is proved.

Without loss of generality, a typical MT is denoted by U_0, the nearest PB that serves U_0 is named the typical PB and denoted by PB_0. The energy link between PB and MT is characterized by path loss but no fading. The number of MTs served by PB_0 is $M_0 \left(M_0 \in Z, M \geq M_0 \geq 0 \right)$, assume U_0 is the k-th MT served by PB_0 ($1 \leq k \leq M_0$). The transmission power from PB_0 to U_0 is denoted by $P_{0,k}$, the received power of U_0 is $G_m P_{0,k} d_{0,k}^{-\alpha}$, where $d_{0,k}$ is the Euclidian distance between U_0 and PB_0 in meter, G_m is the amplify factor in energy beamforming, $\alpha > 2$ is the path-loss exponent in energy link. Considering the power sensitivity of EH [30], we obtain the boundary condition Eq. (9) of the expression. So the received power of U_0 can be written as

$$q_{u_0}^r = G_m P_{0,k} [\max(d_{0,k}, 1)]^{-\alpha} \tag{8}$$

$$s.t. \quad G_m P_{0,k} [\max(d_{0,k}, 1)]^{-\alpha} \geq \varepsilon \tag{9}$$

where ε is the power sensitivity of EH. (If we consider the side-lobe gain of other PBs, when one PB out of PB_0 denoted by PB_j is working, it may have side-lobe gain to U_0. But the amplify factor of the side-lobe G_s is almost one percent of G_m, meanwhile, the distance $d_{j,k}$ between PB_j and U_0 is larger than $d_{0,k}$, so the interference of the side-lobe gain $G_s P_{j,k}[\max(d_{j,k},1)]^{-\alpha}$ is much less than the main-lobe that we ignore it).

We suppose the efficiency factor of energy conversion is equal to one (ideal). Thus the transmission power of U_0 can be given as

$$q_{u_0}^t = q_{u_0}^r \tag{10}$$

2.2 The Uplink cellular network Model

In our model, base stations and MTs are distributed uniformly. MTs in the same cell are independent and the carriers with the corresponding base station are orthographical to each other, the environment is interference-limited. The nearest base station serves U_0 is named the typical base station and denoted by B_0. The date link is characterised by pass-loss and fading, and the channel fading f is assumed to follow exponential distribution (Rayleigh fading), i.e. $f \sim \exp(1)$. Let U_0 sends data to B_0 with power $q_{u_0}^t$, the received signal by B_0 is $q_{B_0}^r = q_{u_0}^t f_0 D_{0,0}^{-\beta}$, where $D_{0,0}$ is the Euclidian distance between U_0 and B_0 in meter, and $\beta > 2$ is the path-loss exponent. It can be expressed as

$$q_{B_0}^r = G_m P_{0,k} f_0 [\max(d_{0,k},1)]^{-\alpha} \cdot [\max(D_{0,0},1)]^{-\beta} \tag{11}$$

The interference comes from MTs out of U_{B_0} :

$$I_0 = \sum_{M_v \in \left(M - U_{B_0}\right)} G_m P_v f_v [\max(d_v,1)]^{-\alpha} \cdot [\max(D_v,1)]^{-\beta} \tag{12}$$

Where M_v is the v-th ($v \in [1, M - nu_0]$) interfering MT to the data link between U_0 and B_0. U_{B_0} is the MTs set that served by B_0, nu_0 is the number of MTs within U_{B_0}. P_v is the transmission power from PB to M_v, d_v is the Euclidian distance between PB and M_v, D_v is the Euclidian distance between B_0 and M_v.

The SINR of the data link is $SINR_0 = \dfrac{q_{B_0}^r}{I_0 + \sigma^2}$, in which σ^2 is the background additive white Gaussian noise (AWGN) variance. The rate of the data link from U_0 to B_0 is given by

$$R_0 = \frac{B}{nu_0} \log_2 \left(1 + \frac{G_m P_{0,k} f_0 [\max(d_{0,k},1)]^{-\alpha} \cdot [\max(D_{0,k},1)]^{-\beta}}{\sum_{M_v \in \left(M - U_{B_0}\right)} G_m P_v f_v [\max(d_v,1)]^{-\alpha} \cdot [\max(D_v,1)]^{-\beta} + \sigma^2} \right) \tag{13}$$

Where B is the bandwidth of the base station.

3. Problem Formulation

In this section, we first introduce the uplink rate maximization problem, then solve the problem with the WFOPAS algorithm.

3.1 The Uplink Rate Maximization Problem

Considering the energy side, M MTs have been divided into clusters corresponding to PBs. The number of MTs served by PB_i is M_i ($\sum_{i=1}^{N} M_i = M$). Assume the k-th ($1 \le k \le M_i$) MT served by PB_i is served by BS_j, with Eq. (13)， The sum-rate of the i-th MT cluster is

$$\sum_{k=1}^{M_i} \frac{B}{nu_j} \log_2 \left(1 + \frac{G_m P_{i,k} f_{j,1} [\max(d_{i,k},1)]^{-\alpha} . [\max(D_{j,1},1)]^{-\beta}}{\sum_{M_v \in \left(M - U_{B_j} \right)} G_m P_v f_v [\max(d_v,1)]^{-\alpha} . [\max(D_v,1)]^{-\beta} + \sigma^2} \right) .$$ We will use the

Uplink Rate (UR) as the performance metric, which is the MT's average rate and defined as

$$UR = \frac{1}{M} \sum_{i=1}^{N} \sum_{k=1}^{M_i} \frac{B}{nu_j} \log_2 \left(1 + \frac{G_m P_{i,k} f_{j,1} [\max(d_{i,k},1)]^{-\alpha} . [\max(D_{j,1},1)]^{-\beta}}{\sum_{M_v \in \left(M - U_{B_j} \right)} G_m P_v f_v [\max(d_v,1)]^{-\alpha} . [\max(D_v,1)]^{-\beta} + \sigma^2} \right) \quad (14)$$

To minimize the on-grid energy consumption, consider the situation that the system powered by renewable energy only, and green energy cooperation has not been implemented yet. Consequently, the uplink rate maximization problem can be formulated as $P1$:

$$\max_{\{P_{i,k}\}} \quad \frac{B}{M} \sum_{i=1}^{N} \sum_{k=1}^{M_i} \frac{1}{nu_j} \log_2 \left(1 + \frac{G_m P_{i,k} f_{j,1} [\max(d_{i,k},1)]^{-\alpha} . [\max(D_{j,1},1)]^{-\beta}}{\sum_{M_v \in \left(M - U_{B_j} \right)} G_m P_v f_v [\max(d_v,1)]^{-\alpha} . [\max(D_v,1)]^{-\beta} + \sigma^2} \right) \quad (15)$$

$$s.t. \quad \sum_{k=1}^{M_i} P_{i,k} \le E_i \quad \forall i \in [1, \text{N}] \quad (16)$$

$$P_{i,k} \ge 0 \quad \forall i \in [1, \text{N}], \forall k \in [1, \text{M}_i] \quad (17)$$

In P1, the peak summed transmit power constraint and the power non-negativity constraint are imposed in Eq. (16) and Eq. (17), respectively.

Since M, N, B, nu_j, M_i is given, when the sum-rate of each cluster is maximum so as the sum-rate of the network. Thus, P1 can be decomposed to maximize the rate of each cluster, so we equivalently introduce a modified version of P1 as follows:

$$\frac{B}{M} \sum_{i=1}^{N} \left(\max_{\{P_{i,k}\}} \sum_{k=1}^{M_i} \frac{1}{nu_j} \log_2 \left(1 + \frac{G_m P_{i,k} f_{j,1} [\max(d_{i,k},1)]^{-\alpha} . [\max(D_{j,1},1)]^{-\beta}}{\sum_{M_v \in \left(M - U_{B_j} \right)} G_m P_v f_v [\max(d_v,1)]^{-\alpha} . [\max(D_v,1)]^{-\beta} + \sigma^2} \right) \right) \quad (18)$$

$s.t.$ (16), (17)

and the version of P2 is expressed as:

$P2$:

$$\max_{\{P_{i,k}\}} \sum_{k=1}^{M_i} \log_2 \left(1 + \frac{G_m P_{i,k} f_{j,l} [\max(d_{i,k},1)]^{-\alpha}.[\max(D_{j,l},1)]^{-\beta}}{\sum_{M_v \in \left(M - U_{B_j} \right)} G_m P_v f_v [\max(d_v,1)]^{-\alpha}.[\max(D_v,1)]^{-\beta} + \sigma^2} \right) \quad (19)$$

$s.t.$ (16), (17)

Hence, let $i = 1, 2, ..., N$ P1 is the sum of P2, any feasible solution for P2 is also feasible for P1.

3.2 The WFOPAS Algorithm

We solve problem P2 for the optimal power allocation solution among each cluster' MTs. It can be verified that P2 is a convex problem since the objective function is concave. At the same time, all the constraints are linear. Thus, the optimal solution satisfies the KKT conditions, and the Lagrange duality method can be applied to solve this problem optimally [31].

Let $\varphi_i \geq 0, b_{i,k} \geq 0, \forall i \in [1, \mathrm{N}], \forall k \in [1, \mathrm{M}_i]$ be the Lagrange operators associated with each of the power constraints of P2 given in Eq. (16) and Eq. (17). Then, the Lagrange function of P2 can be defined as

$L_i(\{P_{i,k}\}, \{\varphi_i\}, \{b_{i,k}\})$

$$= \sum_{k=1}^{M_i} \log_2 \left(1 + \frac{G_m P_{i,k} f_{j,l} [\max(d_{i,k},1)]^{-\alpha}.[\max(D_{j,l},1)]^{-\beta}}{\sum_{M_v \in \left(M - U_{B_j} \right)} G_m P_v f_v [\max(d_v,1)]^{-\alpha}.[\max(D_v,1)]^{-\beta} + \sigma^2} \right) - \varphi_i \left(\sum_{k=1}^{M_i} P_{i,k} - E_i \right) + \sum_{k=1}^{M_i} b_{i,k} P_{i,k} \quad (20)$$

where $\varphi_i, b_{i,k}$ meet the mutual slack conditions, which is

$$\varphi_i \left(\sum_{k=1}^{M_i} P_{i,k} - E_i \right) = 0, \ i \in [1, \mathrm{N}] \quad (21)$$

$$b_{i,k} P_{i,k} = 0 \quad k \in [1, \mathrm{M}_i] \quad (22)$$

thus, we can solve P2 by solving Eq. (20) equivalently. Solving $\partial L_i / \partial P_{i,k} = 0$, the optimal power allocation $p_{i,k}^*$ can be expressed as a function of Lagrange multipliers

$$p_{i,k}^* = \frac{1}{\varphi_i - b_{i,k}} - \frac{\sum_{M_v \in \left(M - U_{B_j} \right)} G_m f_v [\max(d_v,1)]^{-\alpha}.[\max(D_v,1)]^{-\beta} + \sigma^2}{G_m f_{j,l} [\max(d_{i,k},1)]^{-\alpha}.[\max(D_{j,l},1)]^{-\beta}} \quad (23)$$

When the system powered by renewable energy only, and green energy cooperation has not been implemented yet. The green energy has been used up to maximize the sum-rate of the network, it is easy to obtain $P_i^G = 0$ and $\sum_{k=1}^{M_i} P_{i,k} = E_i$, so $\sum_{k=1}^{M_i} P_{i,k} - E_i = 0$. With Eq. (21) the Lagrange operator φ_i can equal to any nonnegative value. With Eq. (17) and Eq. (22), it can

be easily verified that $b_{i,k} = 0$. Thus, the power distribution reaches a fixed level $1/\varphi_i$, the optimal solution can be obtained as

$$p_{i,k}^* = \max\{(\frac{1}{\varphi_i} - \frac{\sum\limits_{M_v \in (M-U_{B_j})} G_m f_v [\max(d_v,1)]^{-\alpha}.[\max(D_v,1)]^{-\beta} + \sigma^2}{G_m f_{j,1} [\max(d_{i,k},1)]^{-\alpha}.[\max(D_{j,1},1)]^{-\beta}}),0\} \qquad (24)$$

$$\text{s.t.} \quad \sum_{k=1}^{M_i} P_{i,k} = E_i \quad \forall i \in [1,N], \forall k \in [1,M_i] \qquad (25)$$

And how to obtain $p_{i,k}^*$ is given in the WFOPAS algorithm as shown in **Table 2**.

Table 2. Algorithm 1: The WFOPAS algorithm for Solving Problem P2

At the beginning initialize $i=1$.

1: Obtain $E_i, M_i, G_m, d_{i,k}, D_{j,1}, \sigma^2$ ($k=1,...,M_i$) from the CC.

2: Initialize the iteration factor $s=1$,

 a) calculating

$$\lambda_i = \frac{1}{\varphi_i} = \frac{E_i}{M_i - s + 1}[1 + \sum_{i=1}^{M_i - s + 1} \frac{\sum\limits_{M_v \in (M-U_{B_j})} G_m f_v [\max(d_v,1)]^{-\alpha}.[\max(D_v,1)]^{-\beta} + \sigma^2}{G_m f_{j,1} [\max(d_{i,k},1)]^{-\alpha}.[\max(D_{j,1},1)]^{-\beta}}]$$

 b) Calculating

$$P_{i,k} = \lambda_i - E_i . \frac{\sum\limits_{M_v \in (M-U_{B_j})} G_m f_v [\max(d_v,1)]^{-\alpha}.[\max(D_v,1)]^{-\beta} + \sigma^2}{G_m f_{j,1} [\max(d_{i,k},1)]^{-\alpha}.[\max(D_{j,1},1)]^{-\beta}}, \quad k=1,...,M_i - s + 1$$

 c) If $P_{i,k} < 0, \forall k$, set $p_{i,M_i - s + 1} = 0, s = s + 1$, turn to step (a).

3: Until $\forall P_{i,k} \geq 0, (k=1,...,M_i)$, the optimal power allocation scheme for the i-th cluster' MTs has been obtained.

 4: Set $i = i + 1$, turn to step 1.

Until $\forall P_{i,k} \geq 0, (i = N, k=1,...,M_N)$, break.

As a result, we obtain $\{P_{i,k}^*\}$ for all MTs finally, that maximize the sum-rate of the network. Thus P2 have been solved completely.

In the following, we compare the performance of the proposed WFOPAS algorithm and the average power allocation strategy (APAS) used in [12] in a system powered by green energy only, and no green energy cooperation among PBs. During comparing, we consider a two-cell simple network. We set $N=2$ PBs, $S=2$ base stations, $M=3$ MTs. The path-loss exponents are $\alpha = 3$ and $\beta = 3$. We assume the background AWGN variance in every data link are the same and equal to -110 dBm. The amplify factor in MPT beamforming is $G_m = 10$ [12]. For simplification, the bandwidth of base station $B=1$ Hz. The radius of the small cell cellular network is $R = 500$ meter, simulating 100000 times.

In **Fig. 3**, it is visible that the MT's average rate increases with the total harvested renewable energy. Under different SINR threshold ϑ, the performance with WFOPAS is much better than that of APAS. The MT's average rate with WFOPAS is improved about

7%~20% than APAS. This behavior can be explained as follows. With WFOPAS, the transmission power in every PB can be allocated adaptively based on the CSI. In each cluster, more power is distributed to the channels whose CSI are good, and less energy is allocated to the MTs with poor channel conditions. But with APAS, power allocation can't be optimized.

Fig. 3. Average rate VS The total harvested renewable energy

4. The Water Filling Optimized Green Energy Cooperation Management Strategy

So far, we have solved P2, and the WFOPAS algorithm can optimize the MT's average rate of the system. In the following, we focus our study on maximize the rate of the system by use green energy cooperation and WFOPAS algorithm jointly in cellular networks, which powered by green energy and grid together. We will show how to implement green energy cooperation with low complexity.

The difference between WFOPAS and WFOGECMS is focused on two aspects: one is whether adopt green energy cooperation, and the other is the range of the water filling optimization algorithm applied. In the WFOPAS algorithm, green energy has no cooperation, the algorithm is applied in each MT cluster corresponding to PB, and it explains how to allocate E_i among antennas within PB_i. In the WFOGECMS algorithm, green energy cooperation carried out via the CC, and the algorithm is implemented in all MTs of the network at the same time. The WFOGECMS algorithm explains how to allocate Q among all MTs.

4.1 The WFOGECMS Algorithm

Green energy cooperation can be implemented by PBs with extra/ inadequate renewable energy locally injecting/drawing power into/from other PBs via the CC. The direction of the energy flow between the CC and PB is controlled by the CC. The harvested renewable energy is efficiently utilized to maximize the rate, and energy shortage is supplied by grid. The WFOGECMS algorithm is expressed in **Table 3**. Whenever the CSI or $\forall E_i$ changed, the CC recalculates and adjusts the parameters of the system immediately. And the rate of the system can be optimized by the WFOGECMS algorithm.

Table 3. Algorithm 2: The WFOGECMS Algorithm

Whenever CSI or $\forall E_i$ changed, turn to step 1.

    1: MTs select the nearest PB and base station to build pre-access.

    2: Controllers collect information such as: the position of MTs', PBs' and base stations'; the harvested renewable energy E_i in every PB; the access situation of each MT to base station and PB; and the CSI. Then controllers upload the information to the CC.

    3: According to the collected data, the CC calculates $P_i\left(i=1,\ 2,\ \dots N\right)$ for each PB.

    4: With P_i and E_i, the CC calculates the energy status $\Delta E_i = E_i - P_i$ in every PB, and affixes each PB with a green ($\Delta E_i > 0$), white ($\Delta E_i = 0$), or red ($\Delta E_i < 0$) label.

    5: PBs with green/red label inject/draw extra/ inadequate renewable energy into/from other PBs via the CC, and PBs with red label obtain the required green energy from the CC. The shortage is complemented by grid.

    6: MTs charged by PBs and communicate with base stations until the end of the current round, turn to step 1.

4.2 The Mathematic Model of WFOGECMS

In the hybrid cellular network, renewable energy and grid co-exist to power PBs. The CC can get d_j (the distance between MT_j and its nearest PB), D_j (the distance between MT_j and its nearest base station BS_i) $j \in [1, \text{M}]$, and the total harvested green energy Q from the system. The renewable energy is utilized efficiently to maximize the rate of the system. Consequently, the uplink rate maximization problem can be formulated as

$P3$:

$$\max_{\{P_j\}} \quad \frac{1}{M}\sum_{j=1}^{M}\frac{B}{nu_i}\log_2(1+\frac{G_m P_j f_j[\max(d_j,1)]^{-\alpha}.[\max(\mathrm{D}_j,1)]^{-\beta}}{\sum_{M_v \in \left(M-U_{B_i}\right)} G_m P_v f_v[\max(d_v,1)]^{-\alpha}.[\max(\mathrm{D}_v,1)]^{-\beta}+\sigma^2}) \quad (26)$$

$$s.t. \quad \sum_{j=1}^{M} P_j \leq Q \tag{27}$$

$$P_j \geq 0 \quad \forall j \in [1,\mathrm{M}] \tag{28}$$

where P_j is the transmission power from PB to MT_j. We solve problem P3 for the optimal power allocation solution. Similar to P2, the Lagrange duality method can be applied to solve P3 optimally.

Let $\varphi \geq 0, b_j \geq 0, \forall j \in [1, M]$ be the Lagrange operators associated with each of the M power constraints of problem P3 given in Eq. (27) and Eq. (28). Since M, B, nu_i is given, the Lagrange function of P3 can be defined as

$$L(\{P_j\}, \{\varphi\}, \{b_j\})$$

$$= \sum_{j=1}^{M} \log_2(1 + \frac{G_m P_j f_j [\max(d_j, 1)]^{-\alpha} \cdot [\max(D_j, 1)]^{-\beta}}{\sum_{M_v \in (M - U_{B_i})} G_m P_v f_v [\max(d_v, 1)]^{-\alpha} \cdot [\max(D_v, 1)]^{-\beta} + \sigma^2}) - \varphi \left(\sum_{j=1}^{M} P_j - Q\right) + \sum_{j=1}^{M} b_j P_j \quad (29)$$

where φ, b_j meet the mutual slack conditions, which is

$$\varphi \left(\sum_{j=1}^{M} P_j - Q\right) = 0, \quad \forall j \in [1, M] \tag{30}$$

$$b_j P_j = 0 \quad \forall j \in [1, M] \tag{31}$$

Thus, we can solve P3 by solving Eq. (29) equivalently. Solving KKT conditions Lagrange operators $\partial L / \partial P_j = 0$, the optimal power allocation p_i^* can be expressed as a function of Lagrange multipliers

$$p_j^* = \frac{1}{\varphi - b_j} - \frac{\sum_{M_v \in (M - U_{B_i})} G_m f_v [\max(d_v, 1)]^{-\alpha} \cdot [\max(D_v, 1)]^{-\beta} + \sigma^2}{G_m f_j [\max(d_j, 1)]^{-\alpha} \cdot [\max(D_j, 1)]^{-\beta}} \tag{32}$$

When the system powered by renewable energy only, and the green energy has been used up to maximize the rate of the network, it is easy to obtain $\sum_{j=1}^{M} P_j = Q$, with Eq. (30) the Lagrange operator φ can equal to any nonnegative value. With Eq. (28) and Eq. (31) it can be easily verified that $b_j = 0$. Thus, the power distribution reaches a fixed level $1/\varphi$, the optimal solutions can be obtained as

$$p_j^* = \max\{(\frac{1}{\varphi} - \frac{\sum_{M_v \in (M - U_{B_i})} G_m f_v [\max(d_v, 1)]^{-\alpha} \cdot [\max(D_v, 1)]^{-\beta} + \sigma^2}{G_m f_j [\max(d_j, 1)]^{-\alpha} \cdot [\max(D_j, 1)]^{-\beta}}), 0\} \tag{33}$$

$$\text{s.t.} \quad \sum_{j=1}^{M} P_j = Q \quad \forall j \in [1, M] \tag{34}$$

How to obtain p_j^* is given in the WFOGECMS algorithm as shown in **Table 4**.

As a result, we have finally obtained $\{P_j^*\}$ for all MTs, which makes the average rate of network maximal. Thus P3 have been solved completely.

According to **Table 3**, the CC calculates each PB's total transmission power P_i by summing P_j within the same cluster, then jointing E_i calculates ΔE_i. After that, commands are sent to PBs. At last, PBs inject/draw redundant/scanty green energy into/from other PBs via the CC to implement green energy cooperation.

Table 4. Algorithm 3: The WFOGECMS Algorithm for Solving Problem P3

At the beginning initialize $i = 1$.

    1: Obtain $Q, G_m, d_j, D_j, \sigma^2$ (j = 1, 2, ..., M) from the system.

    2: Initialize the iterations factor $s = 1$,

        a)   calculating

$$\lambda = \frac{1}{\varphi} = \frac{Q}{M-s+1}[1 + \sum_{j=1}^{M-s+1} \frac{\sum_{M_v \in (M-U_{B_i})} G_m f_v [\max(d_v,1)]^{-\alpha}.[\max(D_v,1)]^{-\beta} + \sigma^2}{G_m f_j [\max(d_j,1)]^{-\alpha}.[\max(D_j,1)]^{-\beta}}]$$

        b)   Calculating

$$P_j = \lambda - Q.\frac{\sum_{M_v \in (M-U_{B_i})} G_m f_v [\max(d_v,1)]^{-\alpha}.[\max(D_v,1)]^{-\beta} + \sigma^2}{G_m f_j [\max(d_j,1)]^{-\alpha}.[\max(D_j,1)]^{-\beta}}, j = 1, 2, ..., M-s+1$$

        c)   If $P_j < 0, \forall j \in [1, M]$, set $p_{M-s+1} = 0, s = s+1$, turn to step (a).

Until $\forall p_j \geq 0$, the optimal power allocation scheme for all MTs has been obtained.

In the following, we will show the performance of the water level λ in the WFOGECMS algorithm. The results come from calculate. Suppose that there are $N = 10$ PBs, and $S = 10$ base stations in the system. The other parameters are the same as before: $\alpha = 3$, $\beta = 3$, $G_m = 10$ [12], $R = 500$ meter, B=1 Hz, simulation 10000 times. The background AWGN variance in every data link are the same and equal to -110 dBm. In **Fig. 4**, the performance of $\lambda = 1/\varphi$ is presented, which is the water level in the WFOGECMS algorithm. It is visible that λ increases with Q, and decreases with the density of MTs. The smaller the density of MTs and the larger the total harvested green energy, the higher the water level will be.

Fig. 4. The performance of λ VS the density of MTs and Q

5. Simulation Results

In this section, we will verify the theoretical results derived in Section 4 and evaluate the performance of the proposed WFOGECMS algorithm by simulation.

First, we consider a cellular network with $N = 10$ PBs, $S = 10$ base stations, $M = 30$ MTs unless otherwise specified. In addition, $\alpha = 3$, $\beta = 3$, $G_m = 10$ [12], $\vartheta = 1$, $\zeta = 0.9$ [17], $R = 500$ meter. For simplification, B=1 Hz, and the background noise in each data link is -110 dBm, simulation 1000000 times.

Fig. 5 shows the MT's average rate of the system. With the practical energy transfer efficiency $\zeta = 0.9$, the average rate increases with the total harvested renewable energy. It is visible that, with the proposed WFOGECMS algorithm, that 'Joint WFOPAS and green energy cooperation', the average rate is the best among 'Joint APAS and green energy cooperation' scheme and 'No green energy cooperation, WFOPAS only' scheme that given in section 3.2. It is also observed that, when Q is little (smaller than 100 watt), the gap between them is large; with the increase of Q, the gap is getting smaller. It means when the total harvested renewable energy is big enough, the improvement brought by WFOGECMS algorithm is no longer obvious. Thereby, when the total harvested renewable energy is not enough, the WFOGECMS algorithm can bring a significant improvement. Third, the employment of green energy cooperation can bring up to 10% promotion in the MT's average rate than without it, while WFOPAS can get 5.4% improvement than APAS, the benefit with green energy cooperation is more obvious. And we can obtain that the gain of green energy cooperation is more dominant over that of WFOPAS, and "Joint WFOPAS and green energy cooperation" strategy, whose name is WFOGECMS, is optimal.

Fig. 5. The average rate vs Q

Next, we evaluate the performance of the proposed WFOGECMS algorithm and another suboptimal average power allocation strategy with green energy cooperation (APASGEC) scheme in a practical system with N=10 PBs, S=10 base stations, and M=30 MTs. In our simulation, we assume that all PBs are deployed in different position with different renewable energy generation capacities. As shown in **Fig. 4**, the water level λ in the water filling

optimization algorithm is described. In **Fig. 6**, we show the network's sum-rate and on-grid energy consumption performance. It is observed that the WFOGECMS algorithm with $\zeta = 0.9$ is better than APASGEC scheme; as the total harvested green energy Q increases, especially after Q=200 watt, the gap between them becomes smaller quickly. Which shows little gain in the sum-rate and approximate 20% decrease of on-grid energy consumption with WFOGECMS. The improvement of the performance mainly because the CC adjusts the renewable energy allocation among PBs dynamically and employ green energy cooperation adaptively.

Fig. 6. The sum-rate and grid power consumption VS the total harvest renewable energy

Fig. 7. The sum-rate VS the density of MTs

Finally, In **Fig. 7**, we show the sum-rate performance VS the density of MTs with N=10 PBs, and M=30 MTs. It is observed that, firstly, when S=10 base stations, with the density of

MTs' increases, the sum-rate performance in WFOGECMS and APASGEC almost the same, no matter the total harvest renewable energy Q=300 or 3000 watt. That means, when Q is big enough, the increase of Q cannot bring the sum-rate lift. Secondly, when Q=300 watt, the sum-rate performance in the WFOGECMS algorithm with S=20 base stations outperforms APASGEC scheme, but almost the same when S=10 base stations, no matter what the density of MTs is. That means, the increase of S brings a significant increase in the sum-rate. That mainly because: when Q is big enough, power is no longer the most important factor, the bandwidth provided by base stations becomes a bottleneck of the sum-rate lift. And the CC adjusts the renewable energy allocation among PBs dynamically and employ green energy cooperation adaptively. So the increase in the number of base stations brings a significant increase in the sum-rate with WFOGECMS algorithm.

6. Conclusions

In this paper, we proposed a new algorithm joint power allocation optimization and green energy cooperation for designing cellular networks with hybrid energy supplies. By introducing the CC, complexity calculation can be uploaded, and the system parameters can be adjusted by the CC dynamically. Thus, the redistribution of green energy can be implemented easily. With the newly proposed core controller-assisted energy cooperation mechanism among PBs, we formulate the network rate maximization problem in an uplink system. By applying the water filling optimization arithmetic, we develop an efficient solution to optimize the transmit power allocation with low complexity. Furthermore, we show the rate gains by jointly exploiting WFOPAS algorithm and green energy cooperation in cellular networks. It is revealed that, under a practical energy transfer efficiency value, green energy cooperation is beneficial when the harvested renewable energy among PBs is distributed unevenly. And the proposed water filling optimized green energy cooperation management strategy can achieve about 10% gains of MT's average rate and 20% reduction of on-grid energy consumption, the performance of cellular networks with hybrid energy supplies is improved.
